Summary

BACKGROUND: The majority of germ cell tumour (GCT) patients can be cured by orchiectomy followed by active surveillance or subsequent systemic and/or local treatments. There are various guidelines for a structured follow-up including radiographic and clinical examinations.

OBJECTIVE: The Swiss Austrian German Testicular Cancer Cohort Study (SAG TCCS) prospectively evaluates follow-up, indicator of relapse and late toxicities. This is a descriptive analysis; we present baseline characteristics and treatment strategies for the first 299 patients with primary GCT or relapsed GCT after completion of treatment.

RESULTS: Of the patients included in this study, 192 (64.2%) had seminoma and 107 (35.8%) non-seminoma. Mean age was 41 years (standard deviation [SD] 11.7) for seminoma and 31 (SD 9.3) years for non-seminoma patients. Median tumour size was 3.5 cm (interquartile range 2.5–5.0 and 2.3–4.5 in seminoma and non-seminoma, re-

spectively) in both histological groups. Among seminoma patients, 81 (42.2%) had primary tumours >4cm; 154 (80.2%) seminoma patients had stage I, 26 (13.5%) stage II and 12 (6.3%) stage III disease. Fifty-seven (53.3%) non-seminoma tumours were stage I, 29 (27.1%) stage II and 21 (19.6%) stage III. Marker-positive disease was present in 58 (30.2%) seminoma patients and 78 (72.9%) non-seminoma patients. Of 154 stage I seminoma patients, 89 (57.8%) chose active surveillance and 65 (42.2%) adjuvant chemotherapy. Twenty-six (45.6%) stage I non-seminoma patients had high-risk disease; 23 of these were treated with adjuvant chemotherapy and 3 chose active surveillance. Among the 30 (52.6%) low risk stage I patients, all opted for active surveillance. Twelve (46.2%) stage II seminoma patients had radiotherapy, 14 (53.8%) were treated with three to four cycles of chemotherapy. All stage III seminoma patients, and all stage II and III non-seminoma patients were treated with three to four cycles of chemotherapy. Treatment decisions

Correspondence:

were made at the respective centre. Eleven patients did not receive therapy that conformed with guidelines.

CONCLUSION: It is important to enrol GCT patients in prospective studies in general, but also in follow-up studies to assess baseline characteristics, oncological outcome, and long-term toxicity and to validate the performance of follow-up schedules. This is the first time that the distribution of disease, detailed baseline characteristics and the respective treatment of men with GCT is collected in a prospective manner in German speaking countries (Switzerland, Austria and Germany) and therefore patterns of care have been evaluated. SAG TCCS results will inform on future modifications of surveillance schedules and follow-up procedures.

: Trial registration number: NCT02229916 (Clinicaltrials.gov)

Keywords: *seminoma, non-seminoma, active surveillance, follow-up, late toxicity, secondary malignancy, sexual health*

Introduction

Germ cell tumours (GCTs) are rare malignancies, but are the most common solid tumours among men between the ages of 15 and 40 years [1]. Throughout the late 20th century, the increase in incidence has been greatest in men of European descent [2]. About 400 men are diagnosed with GCTs in Switzerland every year [3]. Histologically, GCTs comprises pure seminomas in approximately 60% of patients and non-seminomas in 40% [2]. The majority of GCT patients can be cured by orchiectomy and, if necessary, subsequent local or systemic treatments [4]. Active surveillance is a widely accepted strategy in stage I GCT and incorporates close follow-up, with chemotherapy given only to patients subsequently relapsing, thus avoiding treatment in about 50 to 90% of patients [5, 6]. Alternatively, adjuvant chemotherapy can be administered, especially when high-risk features are present, and this minimises the risk of recurrence to below 5% [7–9]. Overall survival for stage I GCT is close to 100% regardless of the management chosen [6]. In stage IIA and selected stage IIB seminoma radiotherapy is an option, whereas all other metastatic GCTs require cisplatin-based chemotherapy [10]. These therapy strategies result in a 10-year overall survival rate of above 95%. However, strict adherence to treatment guidelines is a prerequisite [11, 12].

Given the excellent prognosis, long follow-up after initial treatment is needed, focusing not only on relapse but also on side effects and long-term toxicities including increased risk of secondary malignancies and cardiovascular morbidity, which can occur years after GCT treatment [13]. An interdisciplinary Swiss working group developed evidence-based recommendations for the follow-up of GCT patients that were later adopted by the German Testicular Cancer Study Group [5, 14–16].

Currently, no treatment and outcome data on GCT patients are available for Switzerland. The National Institute for Cancer Epidemiology and Registration (NICER) covers only part of Switzerland and provides statistics only on incidence and mortality. We believe that in GCT patients, more extensive data collection and analysis is needed to

study outcome and late toxicities. In contrast to the United Kingdom and Scandinavian countries, in Switzerland, Austria or Germany the care of GCT patients is neither standardised nor centralised. The Swiss Austrian German Testicular Cancer Cohort Study (SAG TCCS) is the first study to prospectively evaluate the initial indicators of relapse in GCT patients after completion of curative treatment, to measure the usefulness of the various follow-up examinations and to collect data on late sequelae following treatment, namely impairment of cardiovascular, renal, pulmonary, gonadal, neuronal and cognitive function, psychosocial disorders, sexual health and socioeconomic aspects.

SAG TCCS is in accordance with recommendations for future research strategies in GCT published 2010 by Travis et al. [13]. These recommendations include: life-long follow-up within the setting of a large prospective cohort study to ascertain risks of emerging toxicities and the evolution of known late sequelae; the development of comprehensive risk prediction models; elucidation of the effect(s) of exposure to platinum; assessment of the overall burden of medical and psychosocial morbidity; and the development of evidence-based guidelines for long-term follow-up and interventions.

Here we report the baseline characteristics and the treatment strategies for the first 299 patients enrolled in this cohort in Switzerland, Austria and Germany between January 2014 and July 2017, while prospective registration is currently ongoing. Therapies were chosen at the discretion of the local investigators based on their respective in-house guidelines. We will report on initial indicators of relapse and on late toxicities in a later manuscript.

Materials and methods

The SAG TCCS of consecutive newly diagnosed and relapsed male GCT patients after completion of curative/salvage treatment is a Swiss, German and Austrian multicentre prospective cohort study. In Switzerland, urologists and medical oncologists in private practice, and secondary and tertiary referral centres were made aware of this cohort study with several mailings. In addition, all participants at the Swiss Group for Clinical Cancer Research Genitourinary Project Group semi-annual meetings were approached. Participation is voluntary.

Male patients of any age can be included after giving written informed consent if they have a histologically proven seminoma or non-seminoma and are within 3 months of treatment completion (surgery of primary tumour, adjuvant chemotherapy, chemotherapy, radiotherapy, salvage therapy, resection of residual disease if applicable). Exclusion criteria are pre-existent malignancy within the past 5 years, with exception of previous GCT, and inability for any reason to comply with the trial investigations of the follow-up schedules. Patients are classified into one of nine follow-up schedules based on initial stage and risk factors, as published by Cathomas et al. [5]

Data collection at study inclusion comprises patient baseline characteristics, tumour assessments, treatment strategies and tumour markers, and thereafter mode of relapse detection and stage of disease at relapse. The database is set to assess late toxicities, including secondary malignan-

cies, gathered prospectively at the standardised follow-up visits and investigations for at least 10 years, or until loss to follow-up or withdrawal of consent. Depending on funding and research interest, follow-up can be extended further while the study is ongoing. Data are entered locally in electronic case report forms and saved and analysed centrally at the Institute of Social and Preventive Medicine (ISPM) in Bern, Switzerland. The data collection is in accordance with the Declaration of Helsinki and ethical approval was obtained.

The primary objective of the SAG TCC study will be to determine the diagnostic performance and the clinical impact of a variety of tests, including conventional radiographs, computed tomography scans, abdominal ultrasound, serum tumour markers including alpha-fetoprotein (AFP), human chorionic gonadotropin (HCG) or lactate dehydrogenase (LDH), and clinical signs and symptoms that aim at early detection of relapse after curative therapy with documented complete remission or partial remission.

Secondary objectives will be: to determine the rate and time-point of relapse, and the rate of intermediate and poor-prognosis disease at relapse; to compare patient characteristics at baseline and at relapse; and to assess late toxicity, i.e., secondary neoplasms, cardiovascular risk factors and disease, treatment sequelae due to organ dysfunction following cancer treatment and, finally, sexual health and socioeconomic wellbeing. These data will be published after a longer follow-up.

We used Fisher's exact test for binary/categorical variables and Wilcoxon rank-sum tests for continuous variables. This is a descriptive analysis; we present baseline charac-

teristics and treatment strategies for the first 299 patients within SAG TCCS.

Results

A total of 299 patients were included in 14 Swiss, 1 Austrian, and 1 German centre between 10 January 2014 and 1 September 2017. The majority of patients ($n = 276$) are from Switzerland. The 14 Swiss participating sites are all secondary and tertiary oncology centres; two private urology practices have so far not recruited patients. The German and Austrian sites are tertiary oncology referral centres. Study recruitment status is summarised in [figure 1](#).

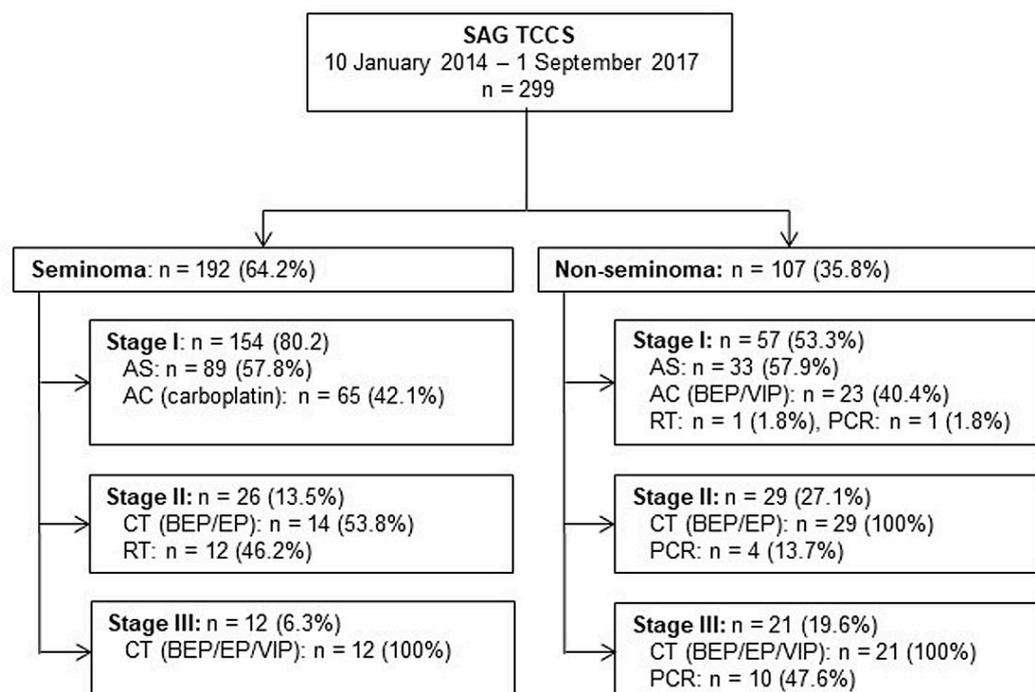

Age, histology and tumour size

Mean age at inclusion was 40.9 (standard deviation [SD] 11.7) and 31.1 (SD 9.3) years in seminoma and non-seminoma patients, respectively. Of the 299 patients, 192 (64.2%) had seminoma and 107 (35.8%) non-seminoma.

Median primary tumour diameter was 3.5 cm in seminoma and 3.5 cm in non-seminoma patients, with 81 (42.2%) of the seminoma patients presenting with a primary tumour ≥ 4 cm. In stage I seminoma, primary tumour size was ≥ 4 cm in 62 (40.2%) patients. Rete testis invasion (RTI) was found in 89 (46.4%) seminoma patients and 74 (48.1%) patients with seminoma stage I. Lymphovascular invasion (LVI+) was present in 56 (52.3%) non-seminoma patients and 26 (45.6%) non-seminoma patients with stage I.

In SAG TCCS, there is no central pathology review and data are taken from local pathology reports.

Figure 1: Distribution of GCT patients: AC = adjuvant chemotherapy; AS = active surveillance; BEP = bleomycin, etoposide, cisplatin; CT = curative chemotherapy; EP = etoposide, cisplatin; PCR = postchemotherapy resection; RT = radiotherapy; SAG TCCS = Swiss Austrian German Testicular Cancer Cohort Study; VIP = etoposide, ifosfamide, cisplatin.

Tumour markers and stage of disease

Three serum tumour markers have established roles in the management of men with GCT: alpha-fetoprotein (AFP), human chorionic gonadotropin (HCG) and lactate dehydrogenase (LDH). Any marker elevation constitutes marker-positive disease. Post-orchietomy levels of tumour markers are used in risk stratification.

In summary, 58 (30.2%) seminoma and 78 (72.9%) non-seminoma patients had marker-positive disease, and 134 (69.8%) seminoma and 29 (27.1%) non-seminoma patients had marker-negative disease. All tumour markers (AFP, HCG and LDH) were available for all patients before start of treatment. In stage I and II seminoma, elevated tumour markers were present in 26.0 and 34.6% of patients, respectively; however, in stage III seminoma, 72.7% of patients had marker-positive disease.

Primary extragonadal GCT (retroperitoneal and mediastinal) was present in eight patients, three with seminoma and five with non-seminoma GCTs.

Twenty-five stage II seminoma and all 29 stage II non-seminoma patients were classified as good prognosis according to the International Germ Cell Cancer Collaborative Group (IGCCCG) classification. One stage II seminoma patient was classified as IGCCCG intermediate prognosis.

In stage III seminoma, 9 (75.0%) patients were classified as IGCCCG [17] good and 3 (25.0%) intermediate prognosis. Of the stage III non-seminoma patients, 10 (47.6%) were classified as IGCCCG good, 6 (28.6%) intermediate and 5 (23.8%) poor prognosis.

Baseline characteristics are summarised in tables 1–3.

Treatment

The majority of stage I seminoma patients ($n = 89$, 57.8%) chose active surveillance, and of these 42 (47.2%) presented with neither a tumour size ≥ 4 cm nor RTI. However, 14 (15.7%) patients with a tumour diameter ≥ 4 cm and RTI opted for active surveillance. Adjuvant treatment with one cycle of carboplatin AUC7 (i.e., the dosage reaching an area under the curve of 7 mg/ml/min) was given to 61 (39.6%) stage I seminoma patients. Three (1.9%) patients were treated with two cycles of carboplatin AUC7 and one patient (0.6%) with carboplatin AUC7 and radiotherapy. The majority of patients who received adjuvant treatment for stage I seminoma presented with either a tumour size ≥ 4 cm ($n = 38$, 58.4%), or RTI ($n = 42$, 64.6%) or both ($n = 24$, 36.9%). Thirty-nine (51.3%) of the stage I seminoma patients aged over 40 were treated with adjuvant chemotherapy.

Among patients with stage II seminoma, 11 (42.3%) received three cycles of bleomycin, etoposide and cisplatin (BEP) and 3 (11.5%) patients four of cycles of etoposide and cisplatin (EP). Twelve (46.2%) seminoma stage II patients had radiotherapy, 11 in combination with once cycle of carboplatin AUC7 chemotherapy in the Swiss Group for Clinical Cancer Research (SAKK) 01/10 study. One seminoma stage II patient had radiotherapy only.

Radiotherapy was applied in five (45.5%) stage IIA and seven (70.0%) stage IIB seminoma patients.

Five (41.7%) stage III seminoma patients were treated with three cycles BEP, five (41.7%) patients with four cycles of EP, and one (9.1%) patient received two cycles BEP followed by two cycles of etoposide, ifosfamide and cisplatin (VIP) each. One patient was treated in the TIGER study protocol after relapse [18]. One seminoma patient underwent resection of residual disease after chemotherapy completion.

Of the stage I non-seminoma patients, 33 (57.9%) chose active surveillance. All 30 (52.6%) patients without LVI and thus with low-risk disease opted for active surveillance. Twenty-six (45.6%) stage I non-seminoma patients had LVI+ as high-risk feature. Only 3 (11.5%) of these chose active surveillance, whereas 23 (88.5%) were treated with adjuvant chemotherapy consisting of one or two cycles of BEP. One (1.8%) non-seminoma stage IS patient was treated with three cycles of BEP. In one patient with sarcomatoid features on histology, two cycles VIP were given as adjuvant chemotherapy, and one non-seminoma stage I patient (1.8%) was treated with radiotherapy.

Of the stage II non-seminoma patients, 27 (93.1%) were treated with three cycles of BEP, 2 (6.9%) with four cycles of EP and none with radiotherapy. In stage III non-seminoma GCTs, 13 patients (61.9%) were treated with three or four cycles of BEP. Four patients (19.0%) were treated with four cycles of VIP. Two patients (9.5%) received four cycles of EP. One (4.8%) patient was switched to the Group d'Étude des Tumeurs Urogénitales (GETUG) 13 protocol [19] after one cycle of BEP, and one (4.8%) had three cycles of BEP followed by one cycle of EP. Fifteen (14.0%) patients underwent resection of residual disease after completing chemotherapy; most were in stage III.

Summary of treatment is displayed in table 4 for seminomas and table 5 for non-seminoma GCTs.

Health-related and socioeconomic patient characteristics

At inclusion, mean body mass index (BMI) was 25.4 (SD 3.4) and 25.5 (SD 4.1) kg/m², mean blood pressure was 132/81 (SD 15.7/9.9) mm Hg and 130/80 (SD 14.0/11.8) mm Hg in seminoma and non-seminoma patients, respectively.

Testosterone levels after orchietomy, chemo- or radiotherapy were available for only 70 (36.5%) and 33 (30.8%) of seminoma and non-seminoma patients, respectively. Of these, 14 (7.3%) seminoma and 6 (5.6%) non-seminoma patients had abnormally low testosterone values (< 9.72 nmol/l) with a mean value of 5.3 (SD 2.8) and 3.4 (SD 2.8) nmol/l in seminoma and non-seminoma patients, respectively. In seminoma, a total of 43 (22.4%) had semen cryopreservation before treatment. For 53 (49.5%) non-seminoma patients cryopreservation was performed.

Fifteen (7.8%) and 9 (8.4%) of seminoma and non-seminoma patients, respectively, had no or only compulsory education. One hundred and eight (56.3%) and 61 (57.0%), respectively, had finished an apprenticeship, and 14 (7.3%) and 11 (10.3%), respectively, high school. Fifty-two (27.1%) seminoma and 22 (20.6%) non-seminoma patients had a college or university degree. Most patients were em-

ployed at inclusion in SAG TCCS: 176 (91.7%) seminoma and 93 (86.9%) non-seminoma patients.

There were 49 (25.5%) current smokers and 10 (5.2%) current substance abusers in the seminoma population at the time of inclusion. Among non-seminoma patients, 33 (30.8%) were current smokers and 11 (10.3%) current substance abusers.

Discussion

We report first data from SAG TCCS. This is the first tri-national cohort study that prospectively collects data from seminoma and non-seminoma patients after completion of GCT treatment and from start of follow-up, thus providing insight into baseline characteristics and patterns of care. Outcome data will be presented at a later time. In contrast,

many other reports on GCT baseline characteristics and patterns of care were retrospective in nature.

One major limitation of our cohort is that all recruiting sites are secondary or tertiary referral centres. This causes bias and our data may not reflect routine practise and care for GCT patients in Switzerland, Austria and Germany.

The mean age in our cohort was 40.9 years (SD 11.7) for seminoma and 31.1 years (SD 9.3) for non-seminoma patients and compares well with other series [20, 21]. However, in a retrospective analysis from North Texas, a region with a significant native-born and immigrant Hispanic population, Hispanic patients presented with GCT at a significantly younger age (mean \pm SD 29.9 \pm 8.9 years) than

non-Hispanic white (NHW) patients (34.0 \pm 11.2 years). This approximately 5 year age difference was seen both in the institutional cohort and a query to the National Cancer Database [22]. Interestingly, in the retrospective analysis from Germany, the mean age of patients with GCT increased significantly from 28 years (before 1990) to 36 years (2005–2010). Likewise, age shifts were found in both of the histological subgroups. Mean age rose from 34 to 39 years in seminoma and from 26 to 31 years in non-seminoma patients. The aetiology of the increasing age at diagnosis in a predominantly Caucasian population remains unclear [20].

SAG TCCS = Swiss Austrian German Testicular Cancer Cohort Study; SD = standard deviation

In our cohort, 192 (64.2%) seminoma patients and 107 (35.8%) non-seminoma patients were enrolled. In accordance with epidemiological studies, the distribution of seminomas and non-seminoma GCTs has been changing over the years, and pure seminoma has become the more common histology. Interestingly, in the stage I seminoma and non-seminoma cohorts presented by Kollmannsberger et al., an equal distribution between seminomas and non-seminoma tumours was seen [6]. The SAG TCCS cohort is similar to the East Anglian GCT group data (58% seminoma patients in the 1996–2002 period) [23] and Danish na-

tional data with 60% seminomas and 40% non-seminoma tumours among all stage I GCTs [24].

In past decades there has been a significant reduction in size of the primary tumour from 5 to 4 cm, as reported in the East Anglian GCT group database [23]. The German National Seminoma Registry Study (NSR study) reported a mean tumour size in stage I seminoma of 3.67 ± 2.1 cm. In the cohort from North Texas, testicular tumour size was 4.1 ± 2.8 cm in NHW patients compared with 5.9 ± 4.6 cm in Hispanic patients [22]. Both tumour size ≥ 4 cm and RTI were present in 38 of 154 (24.6%) stage I seminoma

ASCT = autologous stem cell transplantation; AUC = area under the curve; BEP = bleomycin, etoposide, cisplatin; EP = etoposide, cisplatin; RT = radiotherapy; RTI = Rete testis invasion; TIGER protocol = 2 × paclitaxel and ifosfamide, 3 × carboplatin and etoposide; VIP = etoposide, ifosfamide, cisplatin. * % of stage; † % of treatment type; ‡ % of prognosis group.

patients in our cohort, compared with 33% in the Spanish Germ-Cell Cancer Group (SGCCG) cohort [25]. In stage I seminoma, tumour size and RTI have been described as risk factors for relapse: presence of both was associated with a 5-year relapse rate of 32% and absence of both with a 5-year relapse rate of 12% [26]. Later studies have not validated both factors, and whereas previously tumour size was used in the form of a cut-off of 4 cm, it is now also postulated to be a continuous variable. However, in a recent publication both tumour diameter >4 cm and RTI were confirmed as independent risk factors for relapse [27]. Furthermore, a systematic literature search and analysis of 19 studies proposed tumour size in stage I seminoma as the most valuable prognostic factor [28].

LVI+ is a risk factor for relapse in non-seminoma stage I. Twenty-six of 57 (45.6%) non-seminoma stage I patients in SAG TCCS were LVI+, whereas in the Swedish and Norwegian Testicular Cancer Group (SWENOTECA) cohort 36% were LVI+ [9].

Fifty-eight (30.2%) seminoma patients presented with marker-positive disease before start of treatment (semicas-tration or salvage chemotherapy after relapse), mostly as elevated HCG (n = 36, 18.8%). In our cohort, the marker-positive rate for stage I seminoma at diagnosis was a little higher than the rate reported by Aparico et al. (26% in SAG-TCCS vs 15%) [29]. In eight seminoma patients (4.2%), AFP was mildly elevated. Theoretically, elevated AFP is a sign of non-seminomatous histology, but it can also be elevated in non-malignant conditions such as alcohol abuse, hepatitis, cirrhosis, biliary tract obstruction and other conditions such as Fanconi anaemia. Some individuals have familial, hereditary, mildly elevated serum AFP levels in the range of 15 to 30 µg/l [30]. Just recently a report on mildly elevated AFP among patients after treatment completion in GCT, among them 4 seminoma patients, was published. The authors postulated that mildly elevated and stable AFP should be managed with surveillance [31]. For seminoma patients the rate of elevated HCG is reported at 20 to 30% in advanced disease and the rate of increased LDH at 40 to 60% in all stages [32].

BEP = bleomycin, etoposide, cisplatin; EP = etoposide, cisplatin; GETUG = group d'étude des tumeurs urogénitales; LVI+ = lymphovascular invasion; RT = radiotherapy; VIP = etoposide, ifosfamide, cisplatin * % of stage † % of treatment type ‡ % of prognosis group

A total of 78 (72.9%) non-seminoma patients showed marker-positive disease, which is in line with the experience of the SGCCG [25]. Our data show elevated AFP and HCG with an equal distribution (55.1% each). Any tumour marker was elevated in stage I, II and III in 64.9, 75.9 and 90.5% of patients, respectively. These results are comparable to published data [32].

More seminoma patients were diagnosed in stage I compared with non-seminoma patients ($n = 154$, 80.2% and $n = 57$, 53.3%). Seminoma stage I represented >50% of all GCT cases in our study; therefore recommendations for the management of these patients are particularly important since they affect the largest population [20].

As to treatment decisions, 42.2% of stage I seminoma patients received adjuvant chemotherapy in our cohort. In the prospective SWENOTECA cohort of stage I seminomas, 52.3% of the patients opted for adjuvant chemotherapy, and in the NSR study 57.8% of patients did so [21, 27]. Most recurrences on adjuvant chemotherapy occur within 3 years and can effectively be treated with cisplatin-based chemotherapy, with cure rates of 99% [6]. Adjuvant chemotherapy with carboplatin AUC7 yields a 75% relapse risk reduction to about 4% in stage I seminoma without risk adaption, hence significantly fewer men need chemotherapy or radiotherapy for metastatic disease [33]. Recurrence after initial adjuvant treatment with carboplatin displays the same excellent survival probability as *de-novo* metastatic disease, with a 5-year overall survival of 98% [34]. In a seminal paper, relapse-free rates for patients treated with carboplatin AUC7 were not inferior to adjuvant radiotherapy, but with less short-term toxicity, no significant effect on fertility and almost no long-term toxicity compared with radiation (although long term data are sparse) [35, 36]. Therefore, radiotherapy is no longer standard of care in stage I seminoma and should be reserved for special cases. For stage I seminoma, active surveillance and treatment with adjuvant chemotherapy are options. Shared decision-making with the patient about adjuvant chemotherapy versus active surveillance after orchiectomy should be routine today [37]. It should be taken into consideration that carboplatin offers little risk for short-term toxicity and a significant reduction of relapse risk, but at least an 80% risk of overtreatment. There are insufficient data on long-term toxicity. Relapse, however, necessitates intense salvage chemotherapy with disruption of normal life, impaired quality of life and a substantial risk of long-term toxicity including second malignancies and cardiovascular disease [38]. An adverse prognostic risk factor for GCT-specific mortality is age above 40 years, as salvage therapy cannot be delivered to all such patients [39], thus indicating a potential advantage of adjuvant chemotherapy irrespective of risk factors.

Approximately 56% of high-risk and 86% of low-risk stage I non-seminoma patients are cured after orchiectomy alone [6]. There is a recommendation for active surveillance in low-risk and one cycle of adjuvant BEP in high-risk stage I non-seminoma GCTs [9]. Our data show a majority of stage I non-seminoma patients with high-risk disease ($n = 22$, 88%) were treated with BEP adjuvant chemotherapy and only 3 patients (12%) preferred active surveillance, whereas all patients with low risk disease received active surveillance. There is no rationale for radio-

therapy in non-seminoma stage I tumours and we would not endorse this treatment strategy.

A systematic review and meta-analysis showed that radiotherapy and BEP or EP chemotherapy appear to be equal options in stage IIA and IIB seminoma. However, there is a trend in favour of chemotherapy, with a lower incidence of side-effects and relapse rate, especially in stage IIB [40].

Five patients with stage IIA seminoma (45.5% of all stage IIA) and seven patients with stage IIB seminoma (70% of all stage IIB) were treated with radiotherapy in our cohort.

All patients with advanced disease received poly-chemotherapy and 15 patients underwent resection for residual disease.

Two IGCCCG intermediate-prognosis stage III seminoma patients received either three cycles of BEP or four cycles of EP instead of four cycles of BEP. This is not according to guidelines and represents undertreatment.

One seminoma stage I patient was treated with radiotherapy and carboplatin, one non-seminoma stage I patient had radiotherapy, and another non-seminoma stage I patient received two cycles VIP, all of which are not supported by any data.

We would like to highlight the importance of evidence-based treatment decisions in this highly curative disease.

Prognosis appears to be associated with socioeconomic status. GCT-specific mortality was doubled among US patients diagnosed with seminoma or non-seminoma who were >40 years of age compared with those aged <40 years. Among men with non-seminoma tumours, non-white race and lower socioeconomic status was also associated with increased GCT-specific mortality [39]. In our cohort, 18 (9.4%) and 12 (11.2%) of seminoma and non-seminoma patients, respectively, had no or only compulsory education.

Data on BMI, blood pressure, and testosterone levels serve as a baseline and will be reassessed annually during follow-up.

There are data from a systemic review and meta-analysis on an association of current, chronic, and frequent cannabis use with the development of GCT when compared with never-use of the drug. The strongest association was found for non-seminoma GCTs. In our cohort, twice as many non-seminoma patients as seminoma patients were current substance abusers (10.3 vs 5.2%) [41]. In a recently published cohort study of 49,343 Swedish males born between 1949 and 1951 who underwent extensive medical and psychological assessment at nationwide conscription for the compulsory Swedish military service between 1969 and 1970, no evidence of a significant relation between lifetime “ever” cannabis use and the subsequent development of GCT was found, but “heavy” cannabis use (>50 times in lifetime, as reported at conscription) was associated with a 2.5-fold increased hazard of subsequent GCT. Although the Swedish study and three previous studies [42–44] have shown a relation between frequency and duration of cannabis use and the development of GCT, evidence of a clear dose-response curve – a prerequisite for establishing a persuasive argument for the causal link – is still lacking [45].

GCTs are the only solid tumours that can be cured in the majority of patients with metastatic disease. However, treatment in more advanced disease (intermediate and poor prognosis) is more intensive and cure rates are significantly lower than in the good prognosis group. Active surveillance is a valid strategy in stage I GCT, but early and reliable detection of relapse is essential. It is important to enrol patients in prospective studies to assess not only oncological outcome but also therapy-associated long-term toxicity, and to validate the performance of follow-up schedules and relapse screening modalities stratified by tumour entity, stage and treatment strategy.

This is the first time that the distribution of disease, detailed baseline characteristics and the treatment of men with GCT has been collected in a prospective manner in German speaking countries (Switzerland, Austria and Germany) and therefore patterns of care have been evaluated. Results of SAG TCCS will inform on outcome, future modifications of surveillance schedules and follow-up procedures.

Financial disclosure

The cohort study was made possible by generous financial support from: Ostschweizer Stiftung für klinische Krebsforschung (OSKK). 9000 St. Gallen, Switzerland; Swisscancer, Anna Lisa Stiftung, 6301 Zug, Switzerland; VP Bank Stiftung, 9490 Vaduz, Liechtenstein.
